JOB PERFORMANCE REPORT

State of: Idaho

Name: SALMON AND STEELHEAD
INVESTIGATIONS

Project No.: F-73-R-10

Title: Salmon Spawning Ground Survey

Study No.: 1

Job No.: 2

Period Covered: March 1, 1987 to February 28, 1988

ABSTRACT

Each year, regional fishery biologists survey mayor chinook salmon spawning areas in their respective regions to count the number of redds constructed in trend areas and to obtain age and sex composition data. Current redd counts and long-term trends are made available in this report for trend analysis, management, and research use.

Chinook salmon redd counts in the Salmon River drainage have been declining for the past 30 years. This downward trend, however, appears to be reversing. Redd counts are beginning to stabilize as artificial programs are expanding. Spring and summer chinook salmon redd counts were up in both hatchery-influenced and wild and natural areas in 1987.

Total spring chinook salmon redd counts in the Clearwater River drainage were up 9X from 1986 counts. The South Fork Clearwater River drainage experienced a 12% increase in redd counts this year, and five-year averages show that a steady increase in redds has occurred there over the past 10 years. This trend is due primarily to the Red River rearing pond program. Total redd counts for the Lochsa River drainage declined in 1987 but equal the recent five-year average. Wild and natural chinook salmon spawning streams in the Selway River drainage experienced above-average redd counts in 1987 and appear to be stabilizing.

A temporary weir was installed on Redfish Creek in 1987 to count sockeye salmon returning to Redfish Lake. Due to low flows, however, sockeye were passed above the weir to allow natural spawning to occur in Redfish Lake. Redd count surveys indicated one potential redd at the Redfish Creek inlet.

OBJECTIVES

To monitor salmon spawning escapements in trend areas and to obtain sex and age composition of individual runs.

RECOMMENDATIONS

In order to obtain sex and age composition of individual runs, kelt counts should be conducted three times during postspawning die-off each year in areas where spawning activity is most concentrated.

TECHNIQUES USED

Trend salmon redd counts have been established on selected Clearwater River and Salmon River drainage streams to establish trends in chinook salmon spawning escapement. The single peak count surveys are intended to coincide with the period of maximum spawning activity of a particular stream. Each stream or subbasin is assigned a yearly survey date based on historic observation and counting procedure. The redd counts are made from low flying, fixed-wing aircraft, helicopter, or on foot, depending on the technique best suited for a particular stream. On thirteen selected survey transects, redds were counted by more than one technique for comparative evaluations.

In recent years, new redd count areas have been added by biologists. These sites have not been established for trend count purposes, but are categorized as nontraditional trend count areas with which comparisons can be made in future years.

Nine trend areas in the Salmon River drainage and five in the Clearwater River drainage are categorized as wild chinook areas; that is, not influenced by direct plants of hatchery-reared fish. All other areas in both drainages have received plants of hatchery reared chinook salmon.

Chinook salmon carcass surveys are made on selected streams to identify sex ratios and age composition of individual runs.

Traditionally, sockeye salmon returning to Redfish Lake in the upper Salmon River drainage have been counted from a small boat. The trend area on Redfish Lake is approximately 0.8 km of shoal on the eastern shore near Sandy Beach. During years of low sockeye numbers, a weir is installed on Redfish Creek to trap and count all adults returning to the lake.

FINDINGS

Salmon River Drainage

Since 1957, spring and summer chinook salmon redd counts have declined approximately 83% in the Salmon River drainage (Figures 1 and 2). Gradual increases for both stocks in wild and natural streams have been noted for the last couple of years.

In 1987, overall spring chinook salmon redd counts increased 35X over the 1986 total. This increase was primarily the result of the increase of hatchery-influenced redds in the upper Salmon River drainage (Table 1). Numbers of wild and natural spring chinook salmon redds were up 24% in 1987 (Table 2).

This year, summer chinook salmon redd counts were the highest on record since 1974. In wild areas, redd counts were up 26% over the 1986 counts (Table 3), and redd counts doubled in hatchery-influenced streams (Table 4).

Length frequency and age composition of summer chinook salmon kelts recovered in the South Fork Salmon River drainage are reported in Tables 5 and 6.

Table 7 reports information on spring chinook salmon carcasses recovered in tributaries of the Middle Fork Salmon River.

Unclassified chinook salmon spawning ground surveys for the Salmon River drainage are reported in Table 8.

Chinook salmon redd counts for nontraditional trend areas in the Salmon River drainage are listed in Table 9.

Clearwater River Drainage

Wild and natural spring chinook salmon redd counts in the Clearwater River drainage have decreased dramatically since the early 1970s (Table 10). The recent five-year average is the lowest on record for the past 20 years. However, redd counts since 1981 have more or less stabilized at the reduced level (Figure 3).

Redd counts in hatchery-influenced areas of the Clearwater River drainage were up 9X in 1987, resulting in the second highest count in ten years (Table 11). The five-year average increased by 791, and runs appear to be stabilized (Figure 3). Redd counts in the South Fork Clearwater River, particularly Red River, have made the greatest impact on the Clearwater River drainage numbers. The South Fork Clearwater River contributes 67.3% of all redds (including wild and natural) observed.

Length frequency distribution of 517 chinook salmon kelts recovered in Red River are listed in Table 12.

Nontraditional chinook salmon redd counts in the Clearwater River drainage for 1987 are listed in Table 13.

Techniques Evaluation

Overall, use of helicopter techniques allowed for the greater numbers of redds counted than fixed wing counts (Table 14). Ground counts were greater than helicopter counts in five of the eight comparable situations and greater than fixed wing counts in four of seven instances.

Sockeye Salmon

From 1954 to 1966, sockeye salmon were counted at the Redfish Creek weir. Ground counts of redds in Redfish Lake have been conducted since 1981. A temporary weir was placed in Redfish Creek from June 5 to September 29, 1987 to count sockeye salmon entering Redfish Lake. Due to low flows and elevated temperatures in the adult holding pond, sockeye salmon were passed above the weir to allow natural spawning to occur in Redfish Lake. A total of seven males and nine females entered Redfish Lake in 1987. Ground surveys were conducted on September 17 and 28, and October 8 and 20 to identify potential spawning redds. No adult sockeye were sited during the four surveys; however, one potential redd was observed near the upper Redfish Creek inlet. Funding for the Stanley Basin sockeye salmon enhancement project was discontinued following the 1987 sockeye spawning run.
